

Seascape Ecology

Lab 04 - Raster Analysis

Ryan Reisinger

2024-10-30

Introduction

Welcome to Seascape Ecology Lab 4. Today we will practice reading in raster data, performing some analyses on those data, making simple maps, and writing out (saving) rasters in different formats.

Remember to refer to the [Geocomputation with R](#) book for more help, as well as [terra's website](#).

Remember that these tutorials are all hosted on github (<https://github.com/ryanreisinger/SOES3056>), where you can also find the data and see the R Markdown file used to make the PDF and HTML output. This will be useful for your assessment.

Remember to set your working directory with `setwd()` before we start.

Bathymetry data

You'll often want to use bathymetry data in your work, be it simple for maps, or for seascape analyses. Bathymetry data are 3D: we have x (longitude) and y (latitude) coordinates, and depth values.

There are a few commonly-used sources for global bathymetry data, including ETOPO (<https://www.ngdc.noaa.gov/mgg/global/global.html>) and GEBCO (<https://www.gebco.net/>). You can manually download these data from the websites, but today we'll try and use the `marmap` package (<https://cran.r-project.org/package=marmap>) to download data from inside RStudio.

If you can't get `marmap` to work (sometimes it doesn't install, or refuses to download files), I have uploaded the files to Blackboard.

First, we need to install `marmap`, and other packages we will use.

```
# Install marmap library
# Note, by setting 'dependencies = TRUE', I am asking R to also install all the packages marmap needs
# to work
install.packages("marmap",
                 repos = "https://cran.rstudio.com/",
                 dependencies = TRUE)

# If necessary, install grec
install.packages("grec",
                 repos = "https://cran.rstudio.com/",
                 dependencies = TRUE)

# Install the viridis package for some more colour palettes
install.packages("viridis",
```

```

repos = "https://cran.rstudio.com/",
dependencies = TRUE)

```

Now, we can load the packages.

```

# Load (attach) the library
library(marmap)

## Registered S3 methods overwritten by 'adehabitatMA':
##   method           from
##   print.SpatialPixelsDataFrame sp
##   print.SpatialPixels         sp

##
## Attaching package: 'marmap'

## The following object is masked from 'package:grDevices':
## 
##   as.raster

```

If that worked, we can now download some bathymetry data.

In their [vignette on importing and exporting data with marmap](#), the authors say:

`getNOAA.bathy()` is the easiest way to load data into R, but it depends on the NOAA download protocol, and one must have an internet connection. However, setting the `keep` argument to `TRUE` will save on disk the data downloaded from the NOAA servers when the function is called for the first time. Any subsequent call to `getNOAA.bathy()` with the same list of arguments (i.e. same longitudes, latitudes and resolution) will preferentially load the dataset saved on disk in the current working directory. This allows the users to run scripts without having to query the NOAA servers and download the same data again and again, making the use of `getNOAA.bathy()` possible even off-line.

NOAA hosts the ETOPO dataset, so this function is going to download it.

Let's reproduce the example in the `marmap` vignette '[Analysing bathymetric data in R with marmap](#)'.

```

# We pass two longitude values and two latitude values to the function to define the extent of the area
papoue <- getNOAA.bathy(lon1=140, lon2=155, lat1=-13, lat2=0, resolution=4)

## Querying NOAA database ...
## This may take seconds to minutes, depending on grid size
## Building bathy matrix ...

# IF THE FUNCTION DOES NOT WORK:
# If you can't get this function to work (sometimes NOAA's servers get overwhelmed), you can
# 'uncomment' (by removing the preceding # sign) and run the following line after downloading the file
# from Blackboard and saving it in a folder inside your working directly, called 'data'.
# (remember to first create the folder if it does not exist

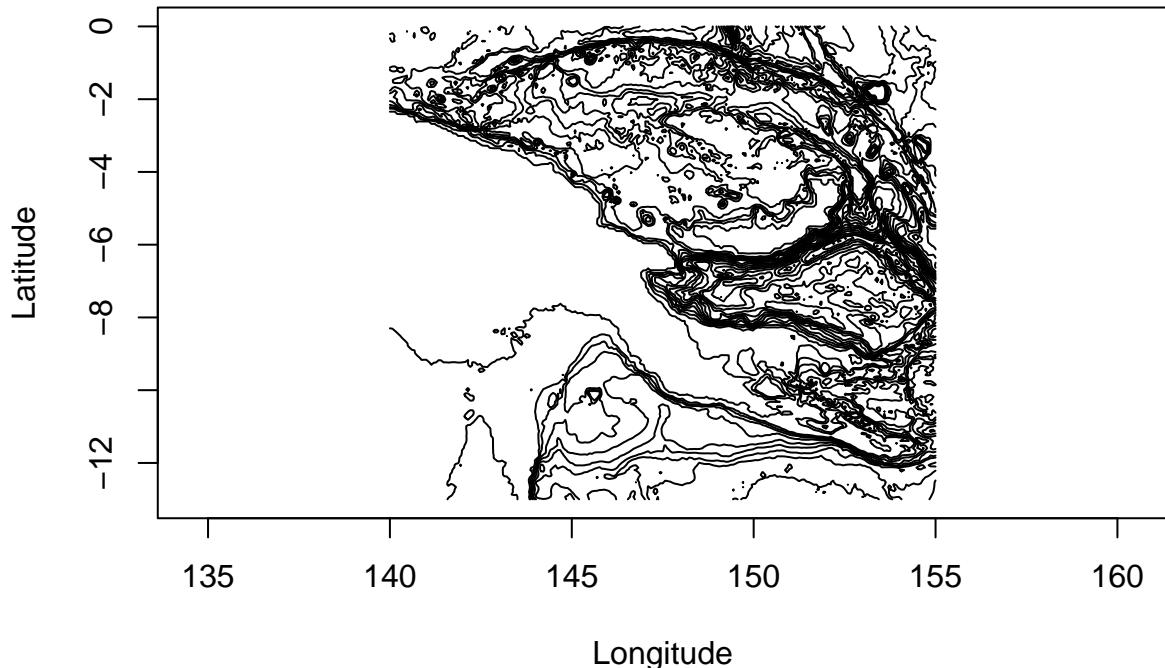

# papoue <- readRDS("./data/papoue.RDS")

# You could also download the file from Github at:
# https://github.com/ryanreisinger/SOES3056/blob/main/Lab%2004/data/papoue.RDS

# This object is a special kind of raster in marmap's own format. We can see that by asking R about the
class(papoue)

```

```
## [1] "bathy"
# marmap has its own plotting method, so we can simply type:
plot(papoue)
```

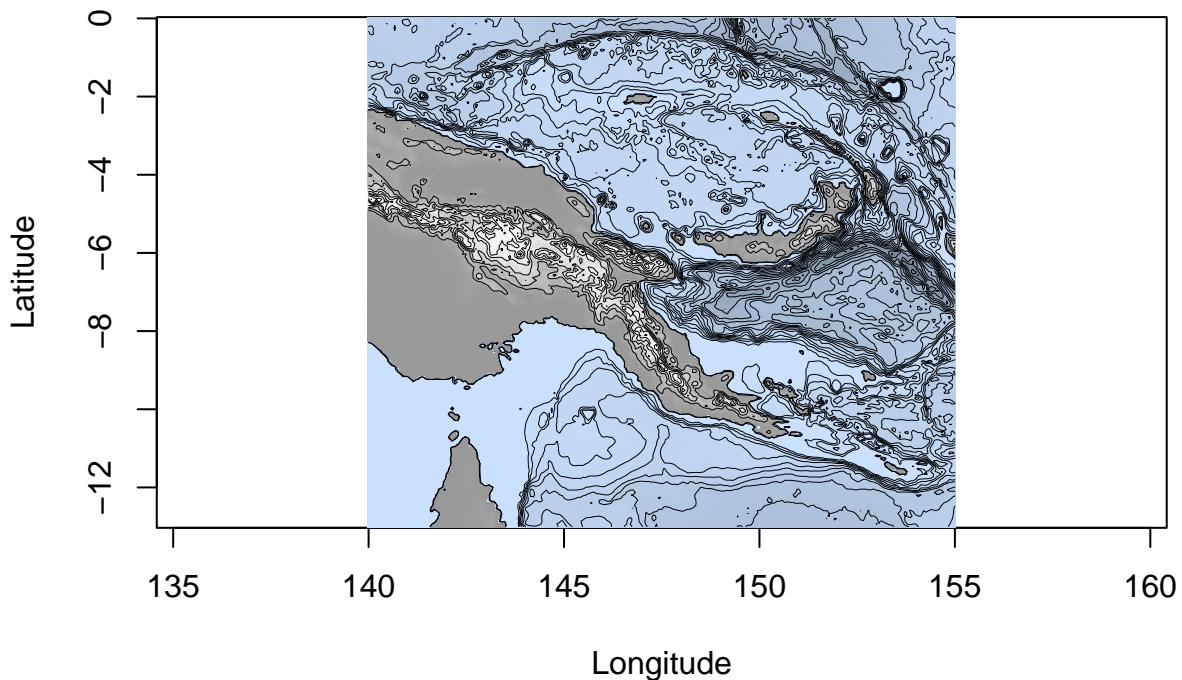

```
# Or we can make the plot a bit nicer, using the examples from marmap
```

```
#Creating color palettes
blues <- c("lightsteelblue4", "lightsteelblue3", "lightsteelblue2", "lightsteelblue1")
greys <- c(grey(0.6), grey(0.93), grey(0.99))

plot(papoue, image = TRUE, land = TRUE, lwd = 0.03, bpal = list(c(0, max(papoue), greys), c(min(papoue)

# Add coastline
plot(papoue, n = 1, lwd = 0.4, add = TRUE)
```

You can work through the marmap vignettes to learn more about making nice bathymetry plots, and doing some simple analyses.

For the moment, we're going to continue our analyses. However, we want to work with a raster in the `terra` package, so let's first convert the class of this object.

```
# First, we'll use one of marmap's functions to convert this object into a raster.
papoue_raster <- marmap::as.raster(papoue)

# See, the class has changed
class(papoue)

## [1] "bathy"

class(papoue_raster)

## [1] "RasterLayer"
## attr(,"package")
## [1] "raster"

# We could use the raster package to analyse this raster now, but remember last week I said that the terra package is better for this kind of analysis.

# First, load terra
library(terra)

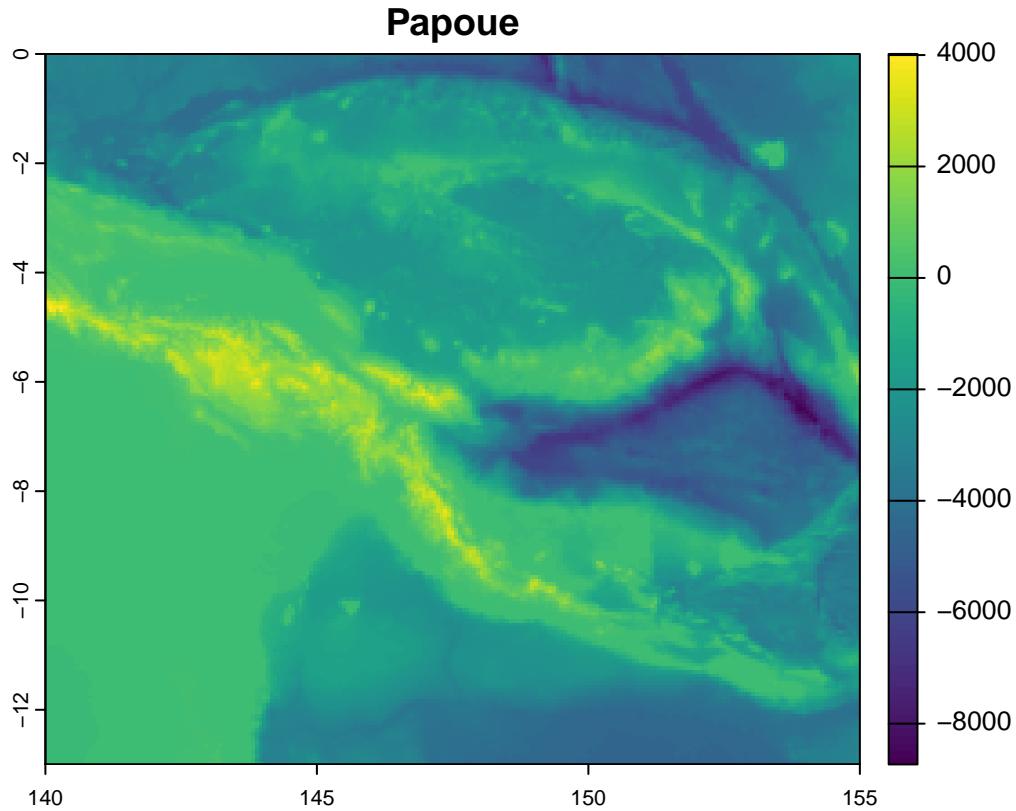

## terra 1.7.78

# Then, convert
papoue_terra <- terra::rast(papoue_raster)

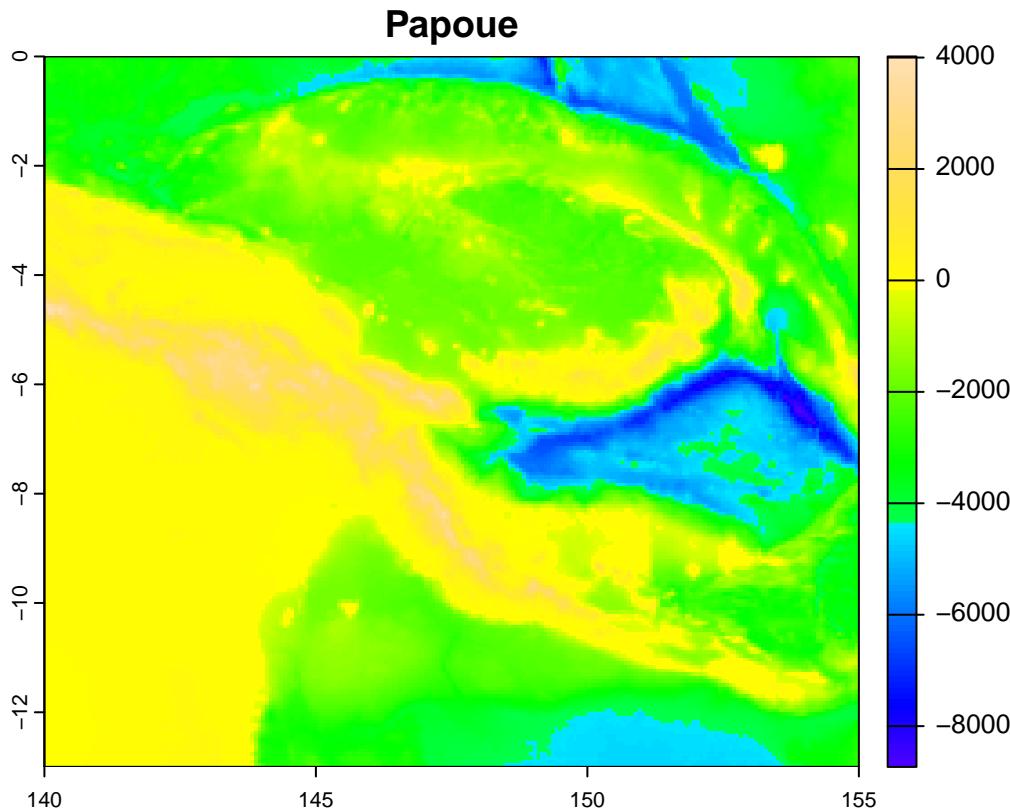

# Notice the class has changed
class(papoue_terra)

## [1] "SpatRaster"
## attr(,"package")
## [1] "terra"
```

```
# Now we can plot it with terra  
# The argument 'main' allows me to give the plot a title  
plot(papoue_terra,  
      axes = TRUE,  
      main = "Papoue")
```

```
# Let's choose better colours  
plot(papoue_terra,  
      axes = TRUE,  
      main = "Papoue",  
      col = topo.colors(125))
```

```
# The colour palette is not that smart, it doesn't understand that negative values should be blue. We'll
```

Let's take a look at some of the characteristics of the data we downloaded. Remember in seascape analyses we're interested in the *extent* and *grain* of the data.

We can get all sorts of information simply by 'printing' the object (typing the name into the R console or running the name from RStudio, or we can use functions to get only the information we want.

```
# Print the object to get some information about it
```

```
papoue_terra
```

```
## class      : SpatRaster
## dimensions : 195, 225, 1 (nrow, ncol, nlyr)
## resolution : 0.06666667, 0.06666667 (x, y)
## extent     : 140, 155, -13, 0 (xmin, xmax, ymin, ymax)
## coord. ref. : +proj=longlat +datum=WGS84 +no_defs
## source(s)   : memory
## name        : layer
## min value   : -8731.732
## max value   : 4019.580
```

Notice the extent and the resolution. Remember that the raster is not projected, so the measurements

We can also get the values using functions.

```
# Resolution
```

```
res(papoue_terra)
```

```
## [1] 0.06666667 0.06666667
```

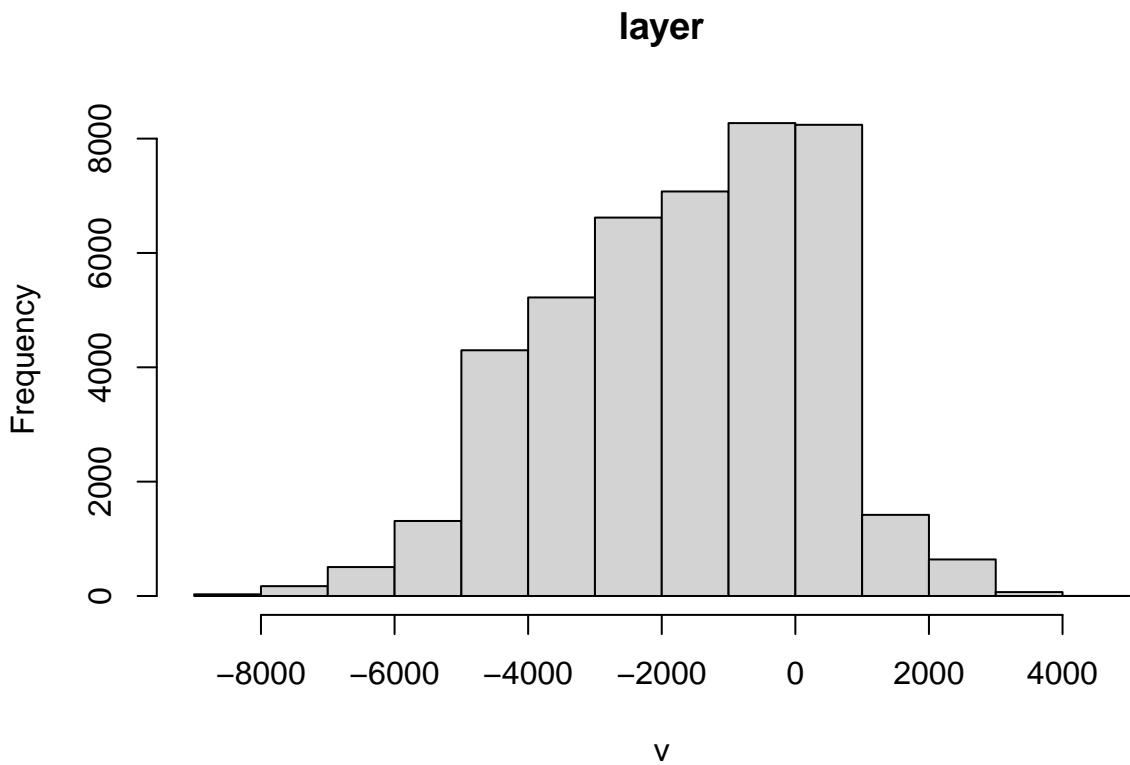

```

# Extent
ext(papoue_terra)

## SpatExtent : 140, 155, -13, 0 (xmin, xmax, ymin, ymax)
# Minimum and maximum value (this is in meters - the values, or z dimension, of the raster can be in any units)
minmax(papoue_terra)

##          layer
## min -8731.732
## max 4019.580
# We could also look at the distribution of values in a histogram
# notice that I type 'terra::hist()' - this tells R I want to specifically use the 'hist()' function from terra
terra::hist(papoue_terra)

```

Conceptual models for seascape analyses

We've talked a lot previously about the two models for seascape analyses:

1. The patch-mosaic model
2. The spatial gradient model

Patch-mosaic

Recall, for the patch-mosaic model we often convert continuous input into **categorical** input by **classification**.

Let's classify our bathymetry raster. For a simple classification exercise, we can decide *a-priori* what we want our categories to be. Although this is simply an example in this lab, you might well do this in practice if you have some basis for the classification.

To use the classification function in **terra**, we first have to define the values.

```

# The classify function in terra has an argument 'rcl', where we can pass a matrix that defines how we ...

# So, let's make a simple one to classify the raster as land and sea. Land values will be positive, and ...

# We can adapt the example given in the the 'classify' functions help page:
?classify # scroll down to the examples

## from-to-becomes
# classify the values into land and sea.
# we can't mix numeric and character values here, so we use 1 to indicate sea and 2 to indicate land.
# all values >= -15,000 and <= -1 become 1, etc.
m <- c(-15000, -1, 1,
       0, +15000, 2)
reclass_matrix <- matrix(m, ncol=3, byrow=TRUE)

# We used huge values for the minum (-15,000) and maximum (+15,000), but remember that we can look up the ...

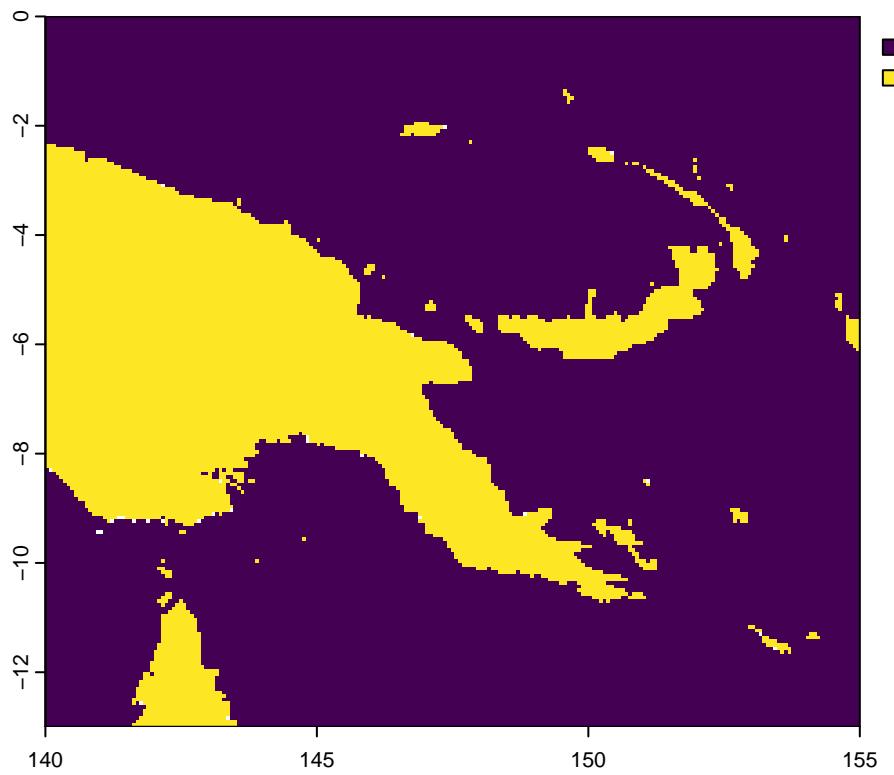

# Have a look at what the matrix looks like
reclass_matrix

##      [,1]  [,2]  [,3]
## [1,] -15000     -1     1
## [2,]      0 15000     2

# Now we can classify our raster
papoue_classified <- classify(papoue_terra,
                                reclass_matrix,
                                include.lowest=TRUE,
                                others = NA) # the argument 'others = NA' means that values which don't fit ...

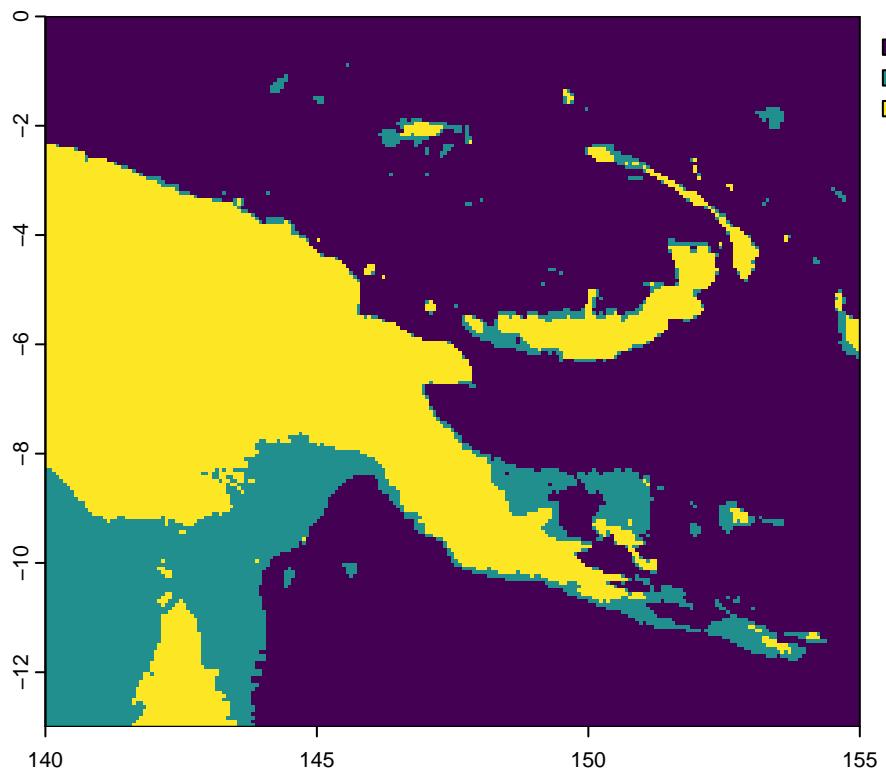

# And let's see what happens when we plot it
plot(papoue_classified)

```

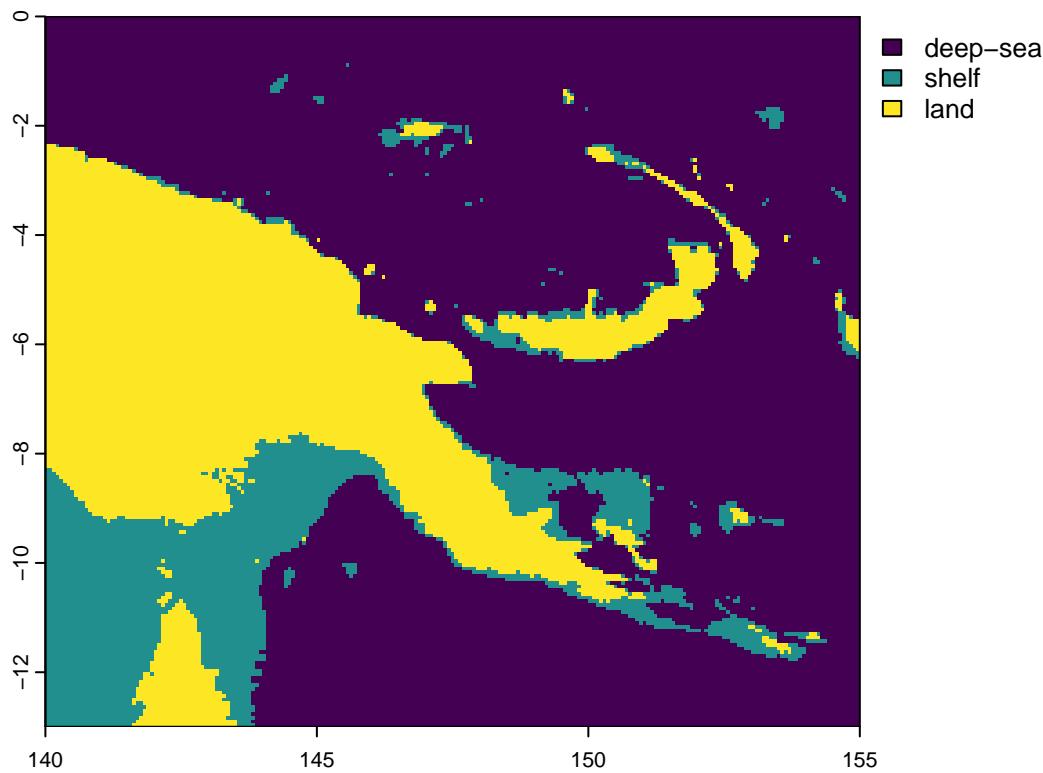

```
# Let's try a slightly more complicated example, where we classify a few bathymetric categories.

# First, we redefine the matrix, then we classify and plot
m <- c(-15000, -200, 1,
       -200, 0, 2,
       0, 15000, 3)
reclass_matrix <- matrix(m, ncol=3, byrow=TRUE)
papoue_classified <- classify(papoue_terra,
                                reclass_matrix,
                                include.lowest=TRUE,
                                others = NA)
plot(papoue_classified)
```

```
# I chose 200 m (-200) to approximately represent the continental shelf edge.  
# We can turn the raster into a truly categorical raster with factor levels (which work similarly to other R objects)  
cls <- data.frame(id=1:3, cover=c("deep-sea", "shelf", "land"))  
levels(papoue_classified) <- cls  
  
# When we plot now, the category names are shown  
plot(papoue_classified)
```

Spatial gradient

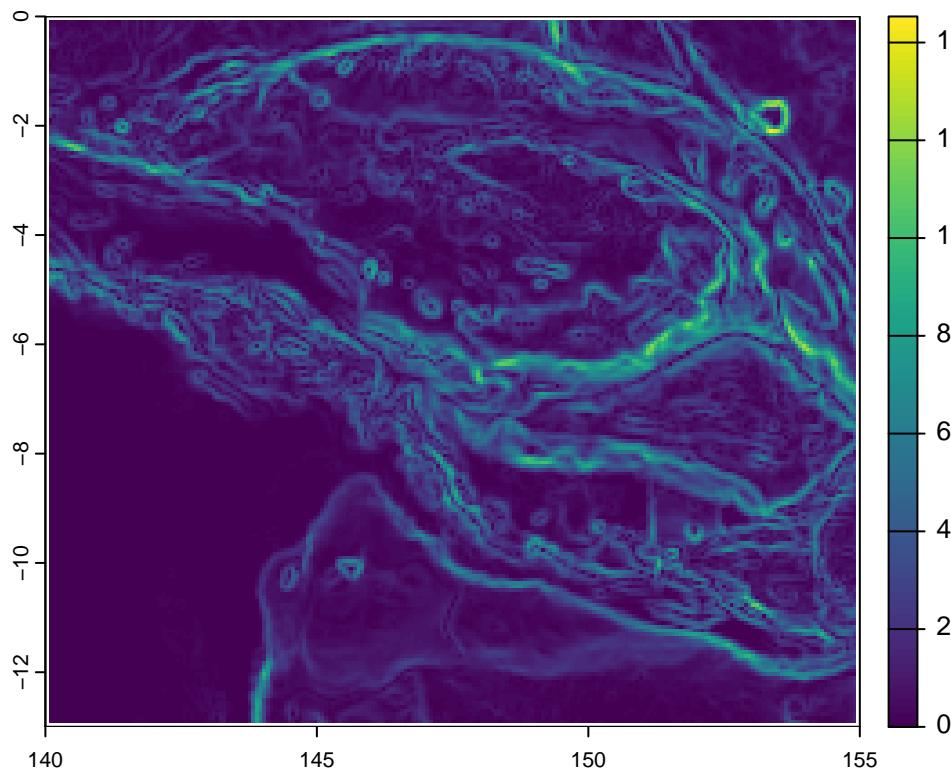

We can also analyse the bathymetry data using the spatial gradient conceptual model. To do this, we use the continuous-value raster - `papoue_terra`.

Recall from Chapter 2 of the seascape ecology textbook (and Lecture 04), that we are often interested in *morphometrics* of the seafloor.

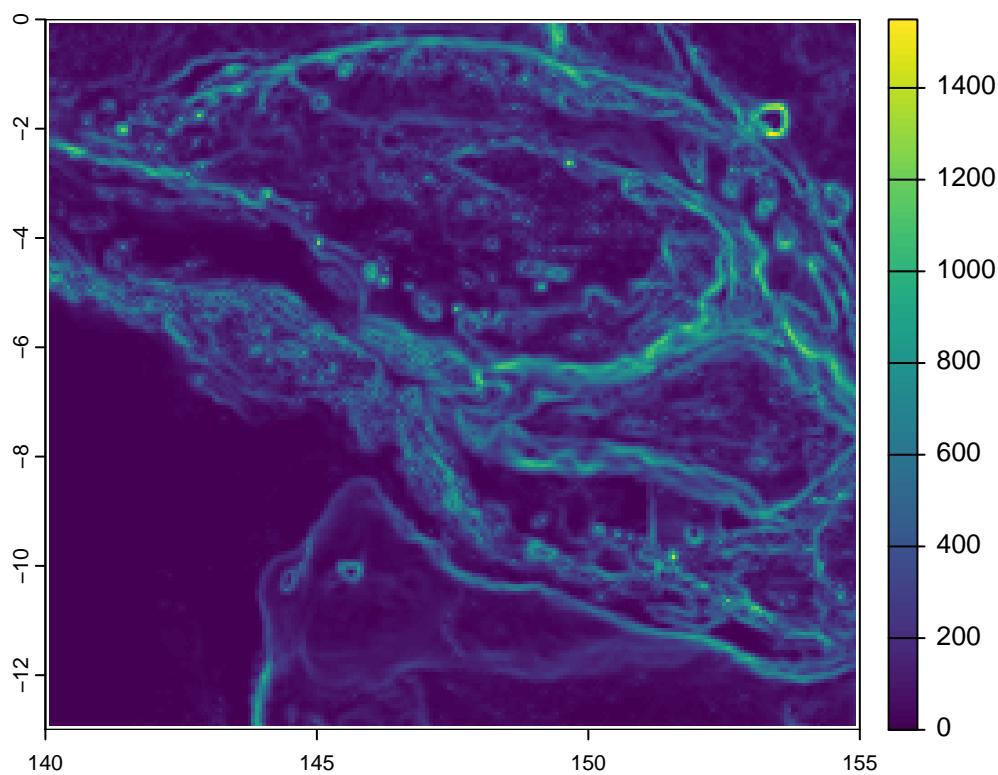

We can easily calculate some simple morphometrics using the `terrain` function in `terra`.

```
# The specific metric we want is set by passing different values to the 'v' argument in the function.

# Slope
plot(terrain(papoue_terra, v = "slope"))
```

```
# notice that I am wrapping the function in a plot call to immediately visualise the result. It is not
# Terrain Roughness Index (TRI)
plot(terrain(papoue_terra, v = "TRI")) # the output is very similar to slope
```

The paper by Phil Bouchet et al., which I mentioned in Lecture 04, has a detailed discussion of different morphometrics and their importance to marine predators: <https://doi.org/10.1111;brv.12130>.

Saving rasters

At some stage we might like to save the rasters we've worked on. We can do that using `writeRaster` (from <https://rspatial.org/terra/spatial/5-files.html#writing-raster-data>).

Use ‘`writeRaster`’ to write raster data. You must provide a `SpatRaster` and a filename. The file format will be guessed from the filename extension. If that does not work you can provide an argument like ‘`format=GTiff`’. Note the argument ‘`overwrite=TRUE`’ and see ‘`?writeRaster`’ for more arguments, such as ‘`datatype=`’ to set the a specific datatype (e.g., integer).

Notice that I am writing the file to a folder called ‘`output`’, so I can keep my working folder neat and tidy.

```
x <- writeRaster(papoue_terra, "output/test_output.tif", overwrite = TRUE)
```

```
x
```

```
## class       : SpatRaster
## dimensions  : 195, 225, 1  (nrow, ncol, nlyr)
## resolution  : 0.06666667, 0.06666667  (x, y)
## extent      : 140, 155, -13, 0  (xmin, xmax, ymin, ymax)
## coord. ref. : lon/lat WGS 84 (EPSG:4326)
## source      : test_output.tif
## name        : layer
## min value   : -8731.732
## max value   : 4019.580
```

And we can read raster files into R thus.

```
rm(x) # remove x from the environment.
x <- rast("output/test_output.tif") # and try reading our file in.
```

Sea surface temperature

Let's take a look at a dynamic variable – sea surface temperature (SST).

There are many sources for sea surface temperature. In a future Lab we will look at finding environmental data for your analyses. There are also some R packages that can make the job of downloading and managing those data easier. For example, have a look at [this tutorial](#) and [this one](#) – both use the `rerddap` package (<https://docs.ropensci.org/rerddap/>). Also look at `bowerbird` (<https://docs.ropensci.org/bowerbird/articles/bowerbird.html>), a package designed to create and maintain your own local (i.e., on your own computer) copies of environmental datasets. Today, we'll keep it simple.

I went to the NASA Earth Observations website for sea surface temperature data from Aqua/MODIS: <https://neo.gsfc.nasa.gov/view.php?datasetId=MYD28M>.

MODIS (Moderate Resolution Imaging Spectroradiometer) is a sensor on board NASA's Aqua satellite: <https://modis.gsfc.nasa.gov/>

I chose monthly ('1 mo') data for August 2023, downloaded this as ‘GeoTIFF (raster)’, at 0.1 degrees resolution.

We then click on ‘Download Raw Data’ (double red underline in the screenshot below). You'll need to register (quick and free) to download the data.

I saved the file, called `AQUA_MODIS.20230901_20230930.L3m.M0.SST.sst.9km.nc` in a folder called `data` in my working folder. Remember, we don't want to touch our raw data and we want to keep it separate from things we are working on and manipulating (e.g, the derived raster called `papoue_terra` that I wrote to a file called `test_output.tif` in the `output` folder – that is a derived output).

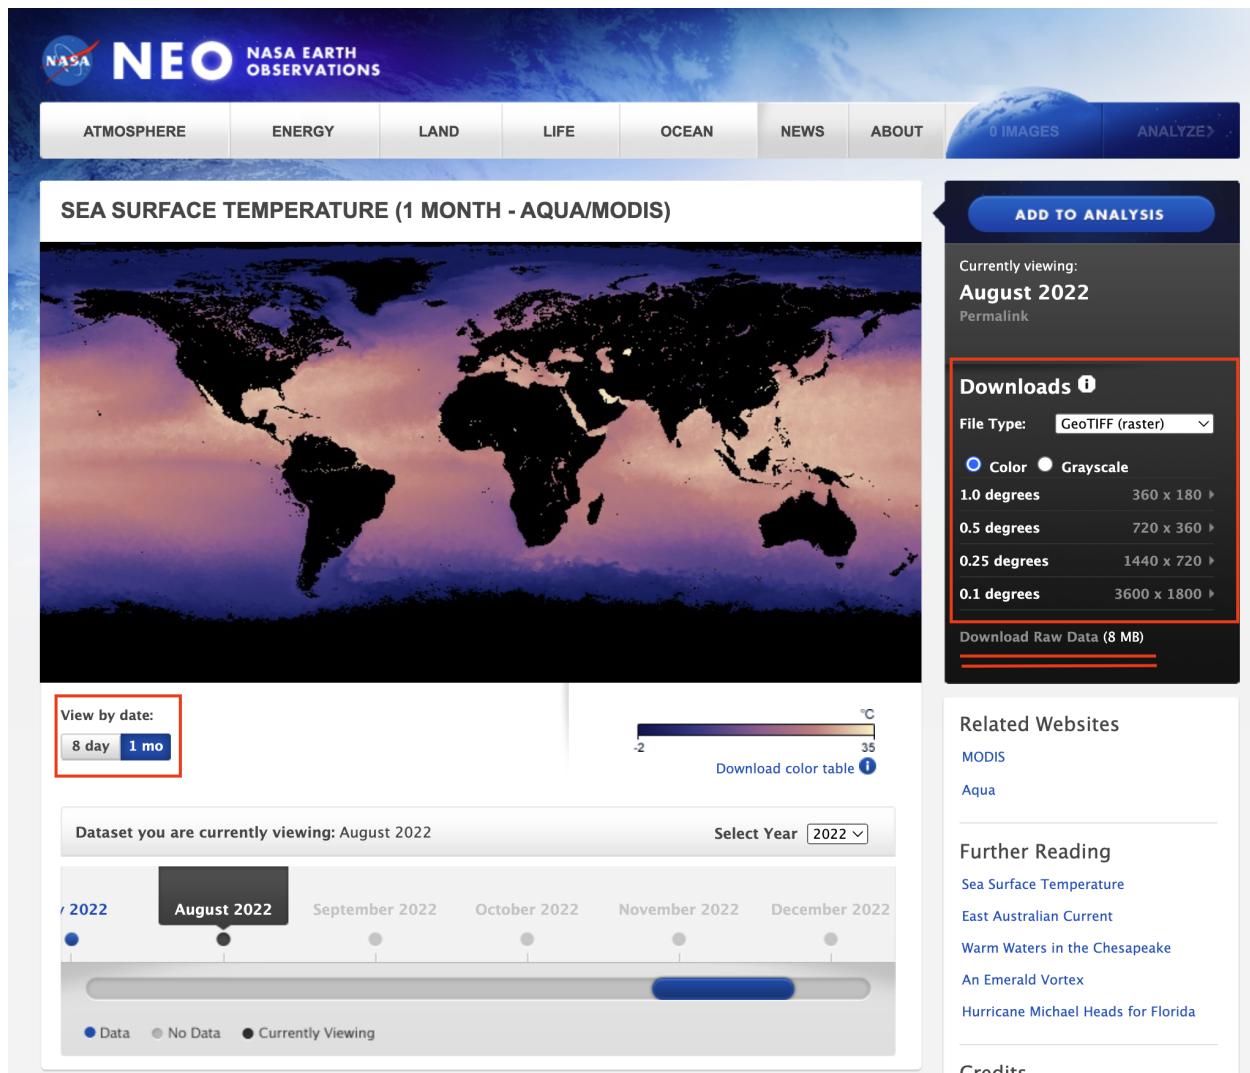

Figure 1: A screenshot of the download page. I've highlighted with red boxes and underling some of the options I chose.

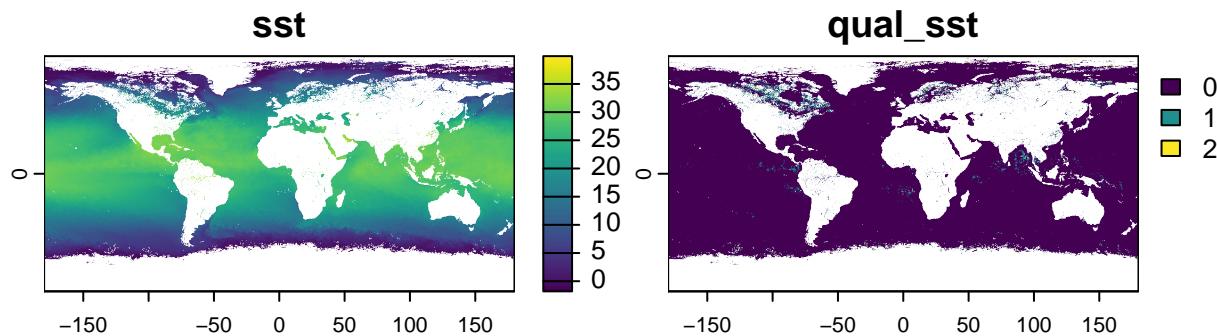

I've put this file on Blackboard if you want to download it from there instead. Remember to put it in a folder called **data** in your working directory. **On Blackboard: Course content -> Labs -> Lab 04 - Raster Analysis -> Files for lab.**

The file has the extension **.nc**, which means it is a NetCDF file, a really common format in oceanography and environmental science. But, this format can be really complicated. Sometimes you are lucky and **terra** can easily understand it. Let's try...

```
# Read in the NetCDF file
sst <- rast("data/AQUA_MODIS.20230901_20230930.L3m.MO.SST.sst.9km.nc")

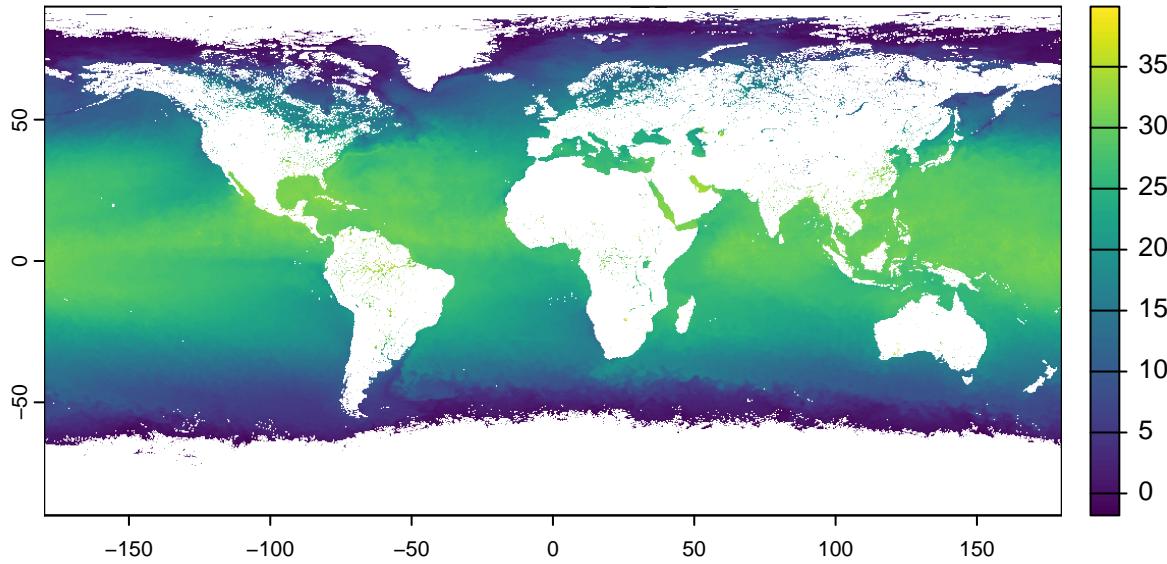

# Look at some properties
sst

## class      : SpatRaster
## dimensions : 2160, 4320, 2 (nrow, ncol, nlyr)
## resolution : 0.08333333, 0.08333334 (x, y)
## extent     : -180, 180, -90, 90 (xmin, xmax, ymin, ymax)
## coord. ref. : +proj=longlat +datum=WGS84 +no_defs
## sources    : AQUA_MODIS.20230901_20230930.L3m.MO.SST.sst.9km.nc:sst
##               AQUA_MODIS.20230901_20230930.L3m.MO.SST.sst.9km.nc:qual_sst
## varnames   : sst (Sea Surface Temperature)
##               qual_sst (Quality Levels, Sea Surface Temperature)
## names      : sst, qual_sst
## unit       : degree_C,
# And plot
plot(sst)
```

```
# You will see the plot has two layers -- we want the first one only
sst <- terra::subset(sst, 1) # Get only layer 1
```

```
# Try plotting it again
plot(sst)
```

Let's remove the rasters from our workspace before we carry on. They can take up a lot of memory. We take two steps. First, we remove the objects with `rm()`, then we also remove any temporary rasters that we can't see, with `tmpFiles()`.

```
# Remove the raster objects
rm(sst)

# Remove any temporary raster files.
tmpFiles(remove = TRUE)
```

We'll discuss getting data (including working with NetCDF) in more detail in a later lab, for the moment, let's read in some SST files that I have downloaded and converted raster for this lab. **On Blackboard:** Course content -> Labs -> Lab 04-> data-> sst_files.

You could also download them from Github: https://github.com/ryanreisinger/SOES3056/tree/main/Lab%2004/data/sst_files

There are seven files (all with a .tif extension. Save these inside a folder called `sst_files` in your data directory.

Once you've done that, verify the files are in the right place using the `list.files()` function. This is a handy function for when you start programmatically accessing lots of files.

```
# Check that you downloaded the files in the right place.
list.files("./data/sst_files")

## [1] "sst_2020-01-01.tif" "sst_2020-01-02.tif" "sst_2020-01-03.tif"
## [4] "sst_2020-01-04.tif" "sst_2020-01-05.tif" "sst_2020-01-06.tif"
## [7] "sst_2020-01-07.tif"
```

There are seven SST files. Each file is the daily sea surface temperature for an area in the North Sea, north-east of the Scottish mainland (I want to reproduce the same area as Figure 3.3 in the Scales et al. chapter).

Let's look at one of these:

```
sst_01 <- rast("./data/sst_files/sst_2020-01-01.tif")

# Check out the resolution, extent and coordinate reference system.
sst_01

## class       : SpatRaster
```

```

## dimensions : 401, 500, 1 (nrow, ncol, nlyr)
## resolution : 0.01, 0.01000056 (x, y)
## extent      : -4, 1, 57.99822, 62.00844 (xmin, xmax, ymin, ymax)
## coord. ref. : lon/lat WGS 84 (EPSG:4326)
## source     : sst_2020-01-01.tif
## name       : sst_2020-01-01
## min value  : 280.868
## max value  : 283.000

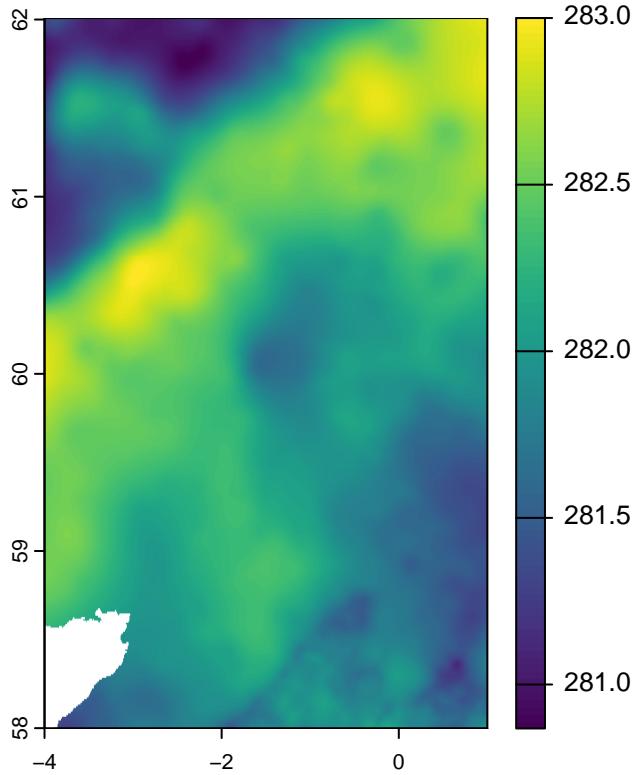

```

Note: The coordinate reference system we get by calling `crs(sst_01)` is
 lon/lat WGS 84 (EPSG:4326)

This is the WGS 84 system, a common one used, for example, for GPS. We can look up the coordinate reference system using the EPSG code (4326) on the [epsg.io](https://epsg.io/4326) website: <https://epsg.io/4326>.

Let's plot our raster

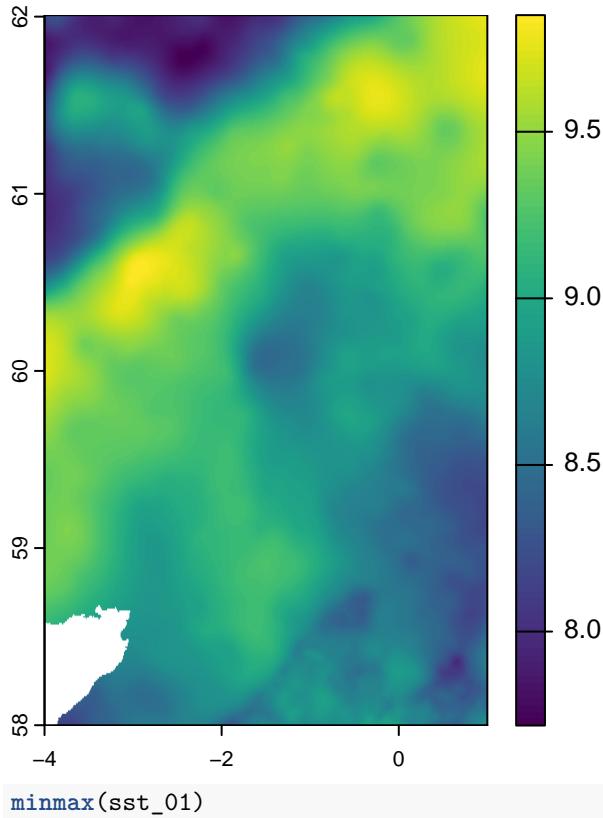

```
plot(sst_01)
```

Notice the values. The temperature is measured in Kelvin, so we need to correct it.

We can use *raster algebra* in various ways. In this case, we can subtract a single value from the whole raster to make the correction.

```
sst_01 <- sst_01 - 273.15 # We simply subtract the correction value
plot(sst_01)
```

```
minmax(sst_01)
```

```
##      sst_2020-01-01
## min     7.718011
## max    9.850000
```

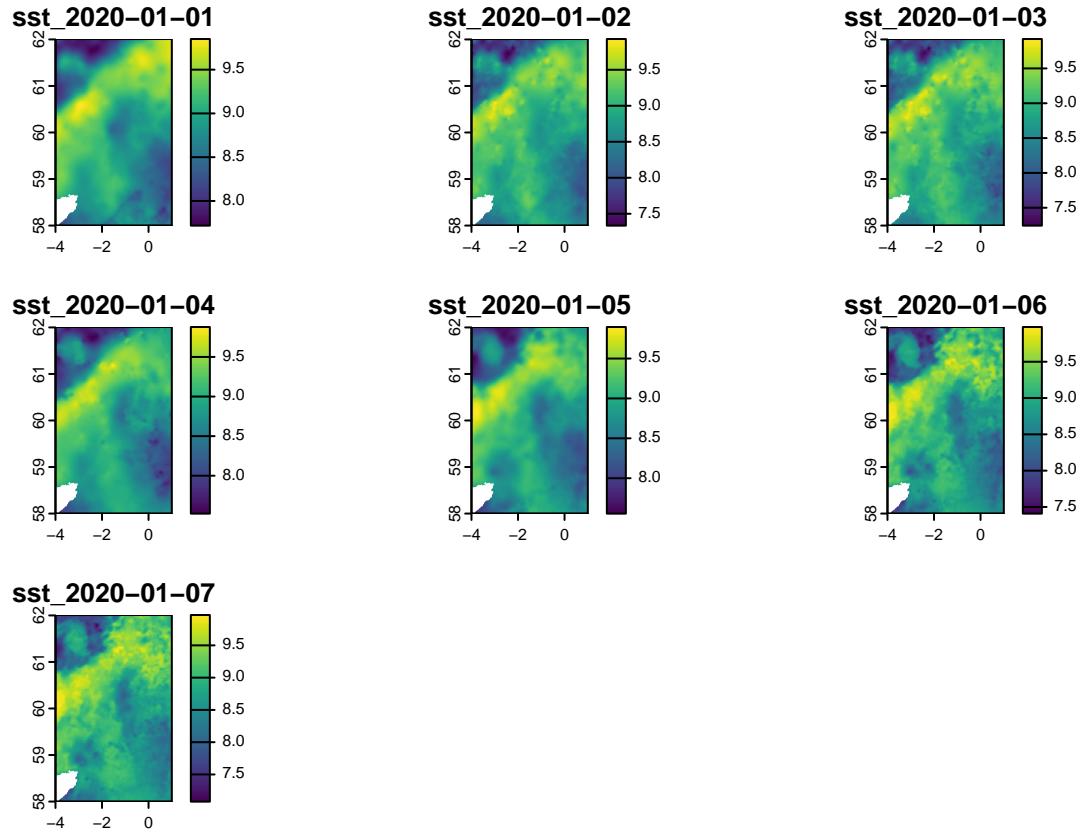

Let's read in the files for all seven days, and correct them as we read them in.

```
sst_01 <- rast("./data/sst_files/sst_2020-01-01.tif") -> 273.15
sst_02 <- rast("./data/sst_files/sst_2020-01-02.tif") -> 273.15
sst_03 <- rast("./data/sst_files/sst_2020-01-03.tif") -> 273.15
sst_04 <- rast("./data/sst_files/sst_2020-01-04.tif") -> 273.15
sst_05 <- rast("./data/sst_files/sst_2020-01-05.tif") -> 273.15
sst_06 <- rast("./data/sst_files/sst_2020-01-06.tif") -> 273.15
sst_07 <- rast("./data/sst_files/sst_2020-01-07.tif") -> 273.15
```

Raster stacks

We can have many layers in a raster, representing different times or different bands in the case of multispectral imagery. This means we can ‘stack’ each daily file into a single ‘raster stack’ with 7 layers.

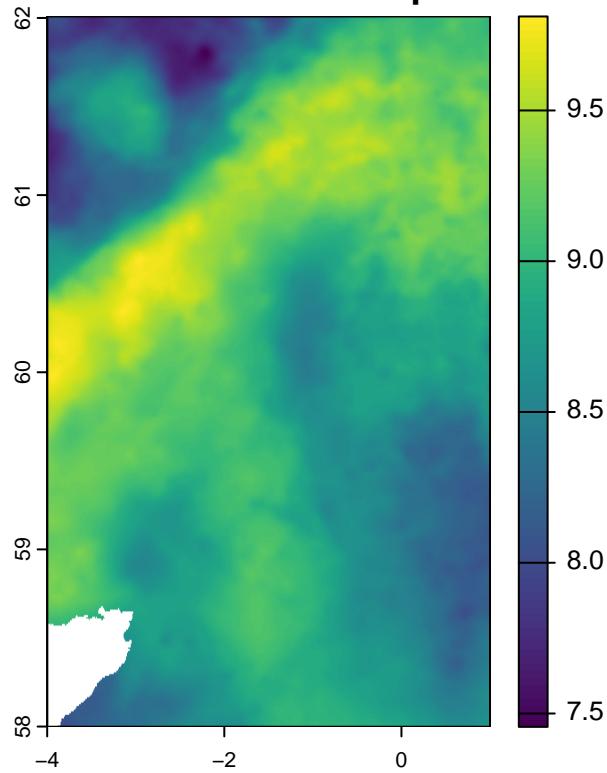

```
# We simply use the c() function
sst_all <- c(sst_01, sst_02, sst_03, sst_04, sst_05, sst_06, sst_07)
plot(sst_all)
```

Again, we can use mathematical functions to work with rasters. For example, we could calculate the average value in each grid cell (pixel) across the whole week. Notice that this will produce a single raster, because we have calculated a single mean for each cell.

```
sst_mean <- mean(sst_all)
plot(sst_mean,
     main = "Mean of sea surface temperature")
```

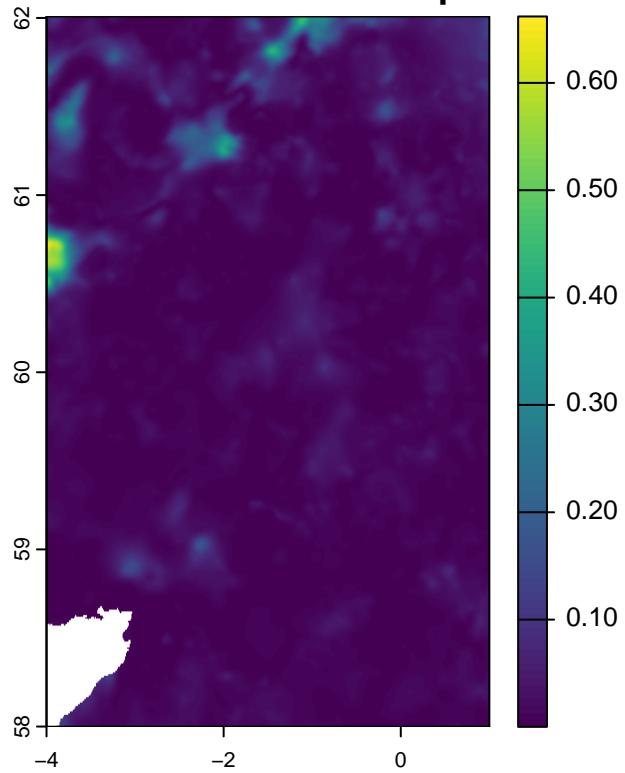

Mean of sea surface temperature

Or we could have looked at the variance to see how variable SST was in each grid cell across the week. In this case we use the `app` function, which applies a function to a raster stack.

```
# we tell the app function we want to use the variance function - var() - with fun = "var"
sst_variance <- terra::app(sst_all, fun = "var")
plot(sst_variance,
     main = "Variance in sea surface temperature")
```

Variance in sea surface temperature

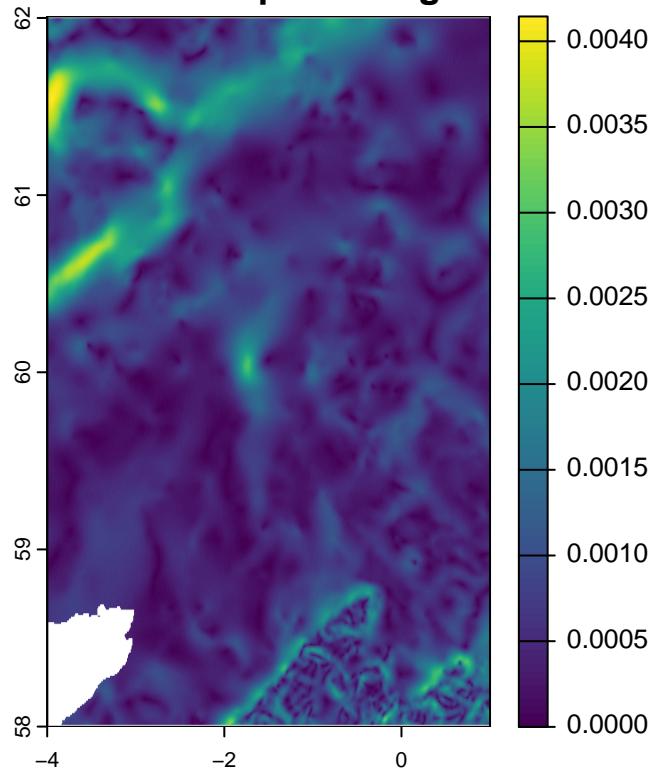

Look at the `terra` tutorial for more examples: <https://rspatial.org/terra/rs/3-basicmath.html>.

Finding spatial gradients

Let's find a spatial gradient in one of the sst rasters. We can use the `terrain()` function that we used earlier, since this is also a kind of gradient (although the output units in this case don't quite make sense).

```
sst_gradient <- terrain(sst_01, v = "slope")
plot(sst_gradient,
     main = "Sea surface temperature gradient")
```

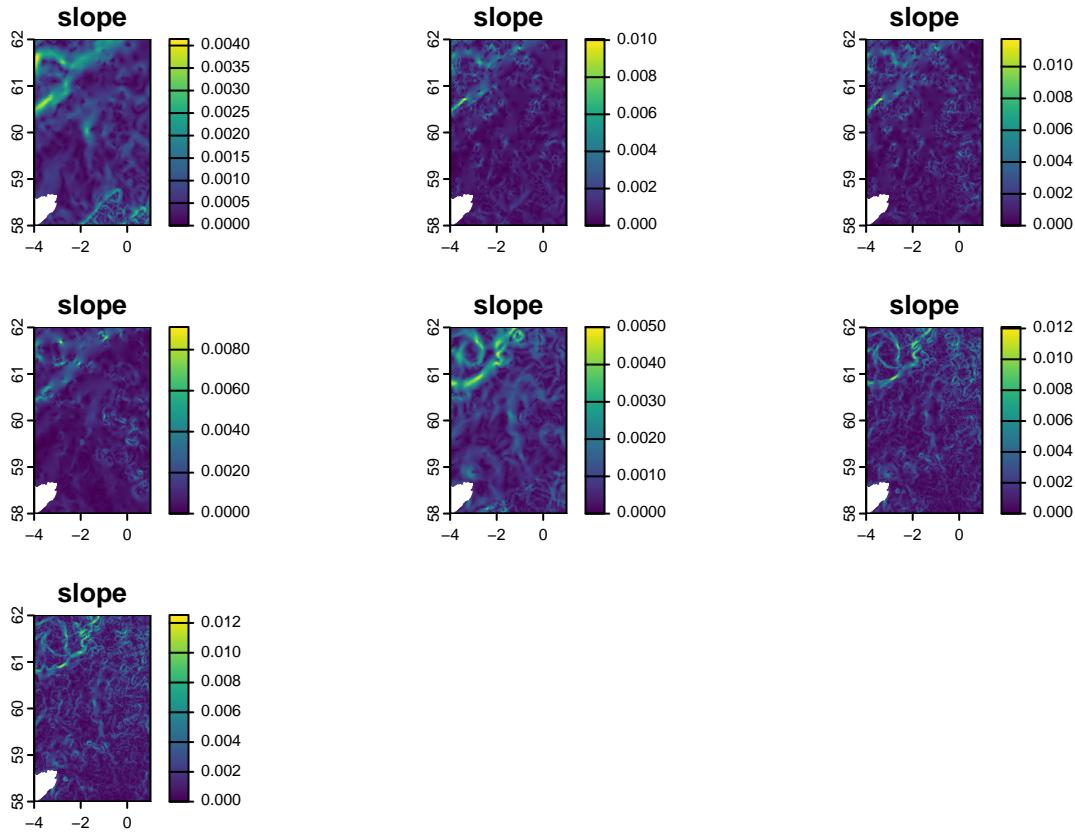

Sea surface temperature gradient

That's starting to look a bit like Figure 3.3 in the Seascape Ecology textbook, right? The green areas are regions with high sst gradient - they are places where SST is changing quickly across space. Ecotones?

We can also apply this kind of function to the whole stack using the `sapp()` function and in this case the function works layer by layer instead of calculating a value in each cell *across* all the layers.

```
# Warning: this will take a while to run
sst_all_gradient <- sapp(sst_all, terrain, v = "slope")
plot(sst_all_gradient)
```

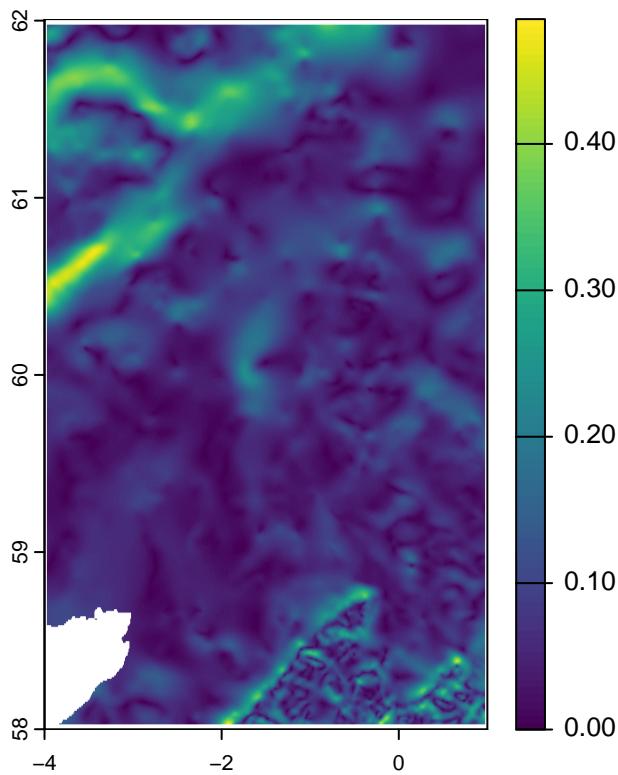

But let's calculate sea surface temperature fronts (also a kind of gradient) using a proper algorithm - Belkin & O'Reilly's (2009) front detection algorithm (<https://doi.org/10.1016/j.jmarsys.2008.11.018>).

For that we'll need the grec package.

```
# Load the grec library we installed earlier
library(grec)

# And run the function
sst_fronts <- getGradients(sst_01)

# And plot
plot(sst_fronts)
```

So, it looks about the same as the raster we calculated with the `terrain` function, but notice that the units are different. They are now in degrees Celsius per km.

Let's make the map a bit better.

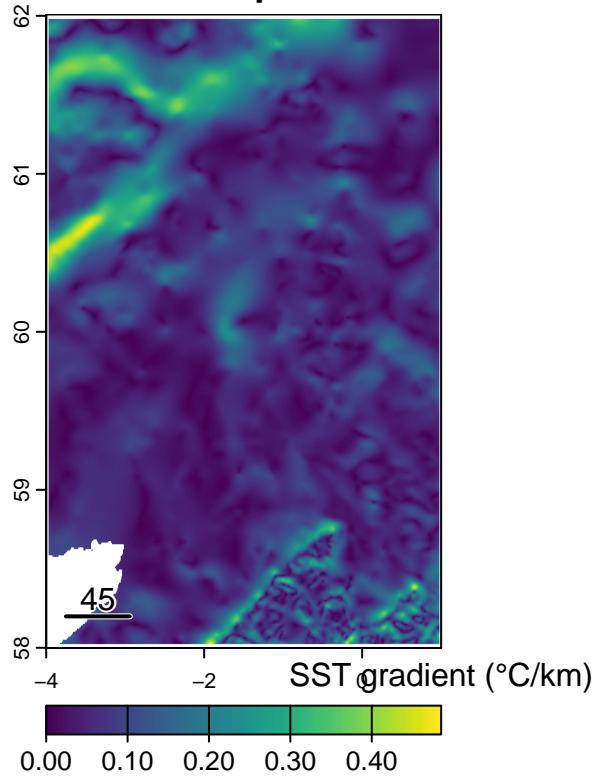

```
# Load the viridis library for more colour palettes
library(viridis)

## Loading required package: viridisLite

# And plot
terra::plot(sst_fronts,
  main = "Sea surface temperature fronts", # main title
  legend = "bottom", # put the legend at the bottom
  plg = list(title = "SST gradient (°C/km)", # a title for the legend
  col = viridis(125)) # use the viridis colour scale

# Add a scale bar
terra::sbar()
```

Sea surface temperature fronts

More reading and practice

For more, continue working on the tutorials from

- Geocomputation with R
<https://geocompr.robinlovelace.net/>
- Spatial Data Science with R and “terra”
<https://rspatial.org/terra/index.html>
